ABSTRACT

The compresional properties of paracetamol tablet formulations containing modified starch (acid hydrolysed), Polyvinylpyrrolidone and maize starch as binders have been investigated. Paracetamol granules obtained by wet massing at varying binder concentrations were compacted using a hydraulic press at different tabletting pressures (28.31-141.56 MNm⁻²). Density measurements and the compression equations of Heckel and Kawakita were used as assessment parameters where the following variables Pₓ, Dₓ, Dₒ, Dᵧ, and Dₘ were investigated. Formulations containing modified starch showed a slower onset of plastic deformation due to a high mean yield pressure while that of PVP showed the highest onset of plastic deformation. Maize starch BP had the lowest Pₓ value indicating the highest total plastic deformation occurring during compression while modified starch had the highest Pₓ value owing to a lesser total plastic deformation showing that there is a correlation between the compression equations of Heckel and Kawakita as assessment parameters and that modified cassava starch could be useful as a binder in paracetamol tablet formulations to produce tablets with desired compresional properties for particular purposes.

Keywords: Modified starch, Polyvinylpyrrolidone (PVP), Heckel equation, Kawakita equation, plastic deformation.

INTRODUCTION

Starch is one of the traditional excipients used in the manufacture of tablets. Depending on the application, specific starches are available for use as binders, diluents, and/or disintegrants. The use of this natural polymeric material is based on its adhesive, thickening, gelling, swelling and film forming properties, as well as its availability. Starch continues to be attractive as a binding material because of its abundant supply, low cost, biodegradability, and ease of chemical modification.

Cassava starch has been found to be useful in the role of a binder in particular tablet formulations. It is however important to characterize the compaction properties of these binders in order to determine the optimum conditions to which they should be subjected during tabletting process. The compression properties of pharmaceutical powders have been characterized using density measurements and the Heckel and Kawakita equations.

The Heckel equation is widely used for relating the relative density, Dₒ of a powder bed during compression to the applied pressure, P. It is written as:

\[ \ln\left[\frac{1}{1-D}\right] = K P + A \]  \hspace{1cm} (1)

The slope of the straight line portion, K, is the reciprocal of the mean yield pressure, Py, of the material. From the value of A, the intercept, the relative density Dₓ can be calculated using the following equation:

\[ Dₓ = 1 - e^{-A} \]  \hspace{1cm} (2)

The relative density of the powder at the point when the applied pressure equals zero, Dₒ, is used to describe the initial rearrangement phase of densification as a result of die filling. The relative density Dₓ describes the phase of rearrangement at low pressures and is the difference between Dₓ and Dₒ:

\[ Dₓ = Dₒ - D₀ \]  \hspace{1cm} (3)

The Kawakita equation is used to study powder compression using the degree of volume reduction (C) and is written as:

\[ C = \frac{(V₀ - Vₚ)}{V₀} = abP/(1 + bP) \]  \hspace{1cm} (4)

The equation, in practice can be rearranged to give:

\[ \frac{P}{C} = \frac{p}{a + 1/ab} \]  \hspace{1cm} (5)

Where V₀ is the initial bulk volume of powder and Vₚ is the bulk volume after compression. The constant a is equal to the minimum porosity of the material before compression while the constant b is related to the plasticity of the material. The reciprocal of b given a pressure term Pₓ which is the pressure required to reduce the powder bed by 50%.

In the present work, a study has been made of the compaction properties of modified cassava starch, used as binder in comparison with those of polyvinylpyrrolidone and maize starch BP in paracetamol tablet formulations.

Paracetamol was chosen because it possesses poor compression properties and therefore requires a binder to form good quality tablets.

EXPERIMENTAL

Material

The materials used were paracetamol powder, maize starch BP, polyvinylpyrrolidone (PVP), hydrochloric acid...
Mohammed et al.  Journal of Drug Delivery & Therapeutics; 2013, 3(1), 11-14

and Talc powder (May and Baker Ltd, England), magnesium stearate (Merck, Germany), cassava starch obtained from the tubers of Manihot esculenta, family: Euphorbiaceae, (prepared in other laboratory). The extraction of the cassava starch was carried out as described by Linus. The method used for the modification was the same as that reported by WIPO.

**Methods**

**Bulk and tapped densities**

A 50g quantity was weighed and transferred into a 100ml measuring cylinder. The cylinder was allowed to fall on a wooden platform from a height of 2.5cm three times at 2 seconds intervals. The volume occupied by the starch was recorded as the bulk volume. The cylinder was then tapped on the wooden platform until the volume occupied by the starch remained constant. This was repeated three times and average bulk and tapped volumes recorded. The data generated were used in computing the Bulk and Tapped densities as well as Do.

**Compression of Tablets**

Compacts equivalent to 500mg paracetamol were produced by compressing the granules for 30s with predetermined loads (at various compression pressures) using a hydraulic carver press (model, C, serial no 34000 – 289, China). 10 tablets were compacted at each pressure. All read readings are average of 3 measurements. Before each compression, the die (10.5mm in diameter) and flat faced punches were lubricated with a 1% w/v dispersion of magnesium stearate in ethanol. After ejection, the tablets were stored over silica gel in a desiccator for 24h to allow for elastic recovery and hardening to prevent false low yield values and the dimensions of the compact were determined using the digital caliper (Z540 – 1, USA) to the nearest 0.01mm. Their relative densities (D) were calculated using the equation:

\[ D = \frac{V_s}{V_t} \]  

where \( V_i \) is the volume (cm³) of the tablet, and \( \rho_s \) is the particle density (gcm⁻³) of the solid material.

Heckel plots of In(1/1-D) versus applied pressure (P) and Kawakita plots of P/C versus P, were constructed for all binders.

**RESULTS AND DISCUSSION**

The Heckel plots for paracetamol tablets containing 10% (w/v) binder concentration for hydrolysed starch, polyvinylpyrrolidone (PVP) and maize starch BP (MS) gave a linear relationship was obtained with the correlation coefficient of ≥ 0.990 indicating deformation mainly by plastic flow.

The values of the mean yield pressure, Py, D₀, Dₐ and Dₜ for the various binders are presented in Table 2. The ranking for Py was HS > MS > PVP; for D₀ and Dₐ, MS > PVP > HS and for D₀, PVP > MS > HS. The value of D₀ represents the degree of initial packing in the die as a result of die filling for the binders. Hydrolysed starch exhibited the lowest value, this could be attributed to the particle sizes (5-12)µm which are small leading to more mechanical and electrostatic forces to prevent packing. But for maize starch binder which had the highest value of D₀, could be due to the decrease in the electrostatic forces responsible for preventing closer packing of particles.

The value of Dₐ which represents the total degree of packing at zero and low pressures, showed that maize starch had the highest value and HS the lowest. This could still be related to the size and shapes of the particles.

Dₜ represents the phase of rearrangement of the particles in the early stages of compression. The rearrangement of particles occurs more with smaller particle size (PVP) and less with larger and irregular particle sizes (MS and HS). The mean yield pressure Py is inversely related to the ability of the binders to deform plastically under pressure. The results indicate that PVP exhibits the fastest onset of plastic deformation during compression while HS exhibits the slowest rate. This indicates that PVP is soft and ductile and readily deforms plastically during compression. The Kawakita plots for paracetamol tablet formulations containing 10% w/v binder concentration for hydrolysed starch, polyvinylpyrrolidone and maize starch BP are presented in Figure 2. A linear relationship was also obtained at all compression pressures employed with correlation coefficient of 0.999 for all binders. Values of a and ab were obtained from the slope and intercept of the plots respectively. Values of -a gives initial relative density of the formulations Dₜ while Pₚ values of Dₜ and Dₜ are included in Table 2.
The values of $D_1$ which is a measure of the packed initial relative density of the formulations with the application of small pressures or tapping was in the rank order $\text{MS} > \text{PVP} > \text{HS}$. These values were also seen to be slightly higher than the values of loose initial relative density $D_0$.

This is in agreement with previous work\(^\text{11}\). The values of $P_K$, which is an inverse measure of the amount of plastic deformation occurring during the compression process were in the rank order $\text{HS} > \text{PVP} > \text{MS}$. The low value of $P_K$ is indicative of the reduction in cohesion due to the presence of a binder. Binders are generally expected to reduce the cohesiveness and increase flow of granulations\(^3\). A low value of $P_K$ is also indicative of materials that are soft and that readily deform plastically under pressure\(^2\). It has also been established that the lower the $P_K$ value, the more the total plastic deformation ($D_\lambda$) occurring during compression\(^11\). This is the basis of correlation between the Heckel and Kawakita plots. This indicates that HS exhibited the lowest amounts of plastic deformation while MS showed the highest amount of plastic deformation during the compression process.

Comparing the results on compressional characteristics i.e. between $P_y$ and $P_K$, Odeku and Itiola\(^11\) have shown that $P_y$ relates essentially to the onset of plastic deformation during compression, while $P_K$ relates to the amount of plastic deformation occurring during compression process.

**CONCLUSION**

The results of this present work showed that all the formulations containing the different binders deformed by plastic flow\(^5\). It also showed that in tablet formulations, those containing PVP would be more useful in minimizing the problems of lamination and capping especially on high speed tablettting machine with short dwell time for plastic deformation of materials while formulations containing hydrolysed starch as binder would be more useful when high bond strength of the tablet is desired. Thus, hydrolyzed cassava starch could be useful as a binder in paracetamol tablet formulations to produce tablets with desired compressional properties.
